

Linear Pushbroom Cameras

Rajiv Gupta, *Member, IEEE*, and Richard I. Hartley

Abstract—Modeling and analyzing pushbroom sensors commonly used in satellite imagery is difficult and computationally intensive due to the motion of an orbiting satellite with respect to the rotating earth, and the nonlinearity of the mathematical model involving orbital dynamics. In this paper, a simplified model of a pushbroom sensor (the *linear pushbroom* model) is introduced. It has the advantage of computational simplicity while at the same time giving very accurate results compared with the full orbiting pushbroom model. Besides remote sensing, the linear pushbroom model is also useful in many other imaging applications. Simple noniterative methods are given for solving the major standard photogrammetric problems for the linear pushbroom model: computation of the model parameters from ground-control points; determination of relative model parameters from image correspondences between two images; and scene reconstruction given image correspondences and ground-control points. The linear pushbroom model leads to theoretical insights that are approximately valid for the full model as well. The epipolar geometry of linear pushbroom cameras is investigated and shown to be totally different from that of a perspective camera. Nevertheless, a matrix analogous to the fundamental matrix of perspective cameras is shown to exist for linear pushbroom sensors. From this it is shown that a scene is determined up to an affine transformation from two views with linear pushbroom cameras.

Index Terms—Pushbroom sensor, fundamental matrix, satellite cameras, photogrammetry.

1 INTRODUCTION

IN general terms, a pushbroom camera consists of an optical system projecting an image onto a linear array of sensors, typically a CCD array. At any time, only those points are imaged that lie in the plane defined by the optical centre and the line containing the sensor array. This plane will be called the instantaneous view plane or simply *view plane*. Fig. 1 shows the idea behind a pushbroom sensor.

The pushbroom sensor is mounted on a moving platform. As the platform moves, the view plane sweeps out a region of space. The sensor array, and hence the view plane, is approximately perpendicular to the direction of motion. The magnitude of the charge accumulated by each detector cell during some fixed interval, called the *dwell time*, gives the value of the pixel at that location. Thus, at regular intervals of time 1D images of the view plane are captured. The ensemble of these 1D images constitutes a 2D image.

Many times, the camera has no moving parts in it. This fact, which contributes significantly to the superior internal geometric quality of the image, implies that one of the image dimensions depends solely on the sensor motion.

Pushbroom sensors are commonly used in satellite cameras for the generation of 2D images of the earth's surface. Even though the word "pushbroom camera" is most prevalent in the parlance of remote sensing where it is used to describe a specific type of satellite-mounted camera, the image acquisition principle outlined above is applicable to many other imaging situations. For example, the images acquired by side-looking airborne radar (SLAR), certain types of CT projections, and images in many X-ray metrol-

ogy setups can all be modeled as pushbroom images. Before going on to a formalization of this model, we briefly outline two real applications of pushbroom imaging.

Fig. 1. Acquisition geometry of a pushbroom camera.

1.1 SPOT Imagery

SPOT satellite's HRV camera is a well-known example of a pushbroom system. For SPOT, the linear array of sensors consists of a 6,000 pixel array of electronic sensors covering an angle of 4.2 degrees. This sensor array captures a row of imagery at 1.504 ms time intervals (that is, dwell time = 1.504 ms). As the satellite orbits the earth, a continuous strip of imagery is produced. This strip is split into images, each consisting of 6,000 rows. Hence a $6,000 \times 6,000$ pixel image is captured over a nine second flight of the satellite. Such an image covers a square with side approximately 60 km on the ground.

The task of modeling an orbiting pushbroom camera exactly is somewhat complex and several factors must be taken into account.

- By Kepler's Laws, the satellite is moving in an elliptical orbit with the centre of the earth at one of the foci of the ellipse. The speed is not constant, but varies according to the position of the satellite in its orbit.
- The earth is rotating with respect to the orbital plane of the satellite, so the motion of the satellite with respect to the earth's surface is quite complex.
- The satellite is slowly rotating so that it is approximately fixed with respect to an orthogonal coordinate frame defined as follows: the z -axis emanates from the satellite and passes through the centre of the earth; the x -axis lies in the plane defined by the satellite velocity vector and the z -axis; the y -axis is perpendicular to the x - and z -axes. This coordinate frame will be called the *local orbital frame*. During one orbit, the local orbital frame undergoes a complete revolution about its y -axis.
- The orientation of the satellite undergoes slight variations with respect to the local orbital frame.
- The orientation of the view plane with respect to the satellite may not be known.

Some of the parameters of the satellite motion depend on fixed physical and astronomical constants (for example, gravitational constant, mass of the earth, rotational period of the earth). Other parameters such as the major and minor axes and orientation of the satellite orbit are provided as *ephemeris* data with most images. In addition, the fluctuations of the satellite orientation with respect to the local orbital frame are provided as is also the orientation of the view plane. Nevertheless, it has proven necessary for the sake of greater accuracy to refine the ephemeris data by the use of ground-control points.

Even if the orbit of the satellite is known exactly, the task of finding the image coordinates of a point in space is relatively complex. There is no closed-form expression determining the time when the orbiting satellite will pass through a given point in its orbit (time to perigee)—it is necessary to use either an approximation or an iterative scheme. Furthermore, the task of determining at what time instant a given ground point will be imaged must be solved by an iterative procedure, such as Newton's method. This means that exact computation of the image produced by a pushbroom sensor is time consuming.

1.2 X-Ray Metrology

In the most common form of X-ray imagers used for X-ray metrology or part inspection, the object to be viewed is interposed between a point X-ray source and a linear array of detectors. As the object is moved perpendicular to the fan beam of X-rays, a 2D image consisting of several 1D projections is collected. Each image collected in this manner can be treated as a pushbroom image which is orthographic in the direction of motion and perspective in the orthogonal direction. Very good results have been obtained in modeling this imaging setup as a linear pushbroom camera (see [1] for details).

1.3 Overview

In this paper, a linear approximation to the pushbroom model is introduced. This new model very greatly simplifies the computations involved in working with pushbroom images. The key simplifying assumptions made in deriving this camera model are:

- 1) the sensor array is traveling in a straight line and
- 2) its orientation is constant over the image acquisition duration.

Section 2 defines the linear pushbroom model and derives its basic mathematical form. We will show that under the above assumptions—just as with a perspective camera—a *linear pushbroom camera* can be represented by a 3×4 camera matrix M . However, unlike frame cameras, M represents a nonlinear Cremona transformation of object space into image space. In subsequent sections, many of the standard photogrammetric problems associated with parameter determination are solved for the linear pushbroom model. In particular, a linear technique for computing M from a set of ground control points is described in Section 3. Section 4 describes a method of retrieving camera parameters from M . All the algorithms discussed are noniterative, relatively simple, very fast, and do not rely on any extraneous information such as ephemeris data. This contrasts with parameter determination for the full pushbroom model for satellite cameras, which is slow and requires knowledge of orbital and ephemeris parameters.

Apart from computational efficiency, the linear pushbroom model provides a basis for the mathematical analysis of pushbroom images. The full pushbroom model is somewhat intractable as far as analysis is concerned. On the other hand, the agreement between the full pushbroom model and the linear pushbroom model is so close that results of analyzing the linear pushbroom model will be closely applicable to the full model as well.

An important result derived in this paper concerns the relationship of an image point $(u_i, v_i)^T$ in the first image with its corresponding point $(u'_i, v'_i)^T$ in the second image (Section 5). We show that a matrix analogous to the fundamental matrix for perspective cameras [2], [3], [4] exists for linear pushbroom cameras as well. In particular, we prove that there exists a 4×4 matrix F , which we call the *LP (linear pushbroom) fundamental matrix*, such that

$$(u'_i, u'_i v'_i, v'_i, 1)^T F(u_i, u_i v_i, v_i, 1) = 0$$

for all i . We also describe a noniterative technique for deriving F from a set of image to image correspondences.

An example of the theoretical and practical gains achieved by studying the linear pushbroom model is Theorem 5 of this paper, which shows that two linear pushbroom views of a generic scene determine the scene up to an affine transformation. This has the practical consequence that affine invariants of a scene may be computed from two pushbroom views. As was shown in [5], [4], a similar result applies to perspective views where the scene is determined up to projectivity from two views. It is hoped that the linear pushbroom model may provide the basis for the development of further image understanding algorithms in the

same way that the pinhole camera model has given rise to a wealth of theory and algorithms.

The results described in this paper can be used to formulate a complete methodology for stereo information extraction from a set of two or more images of a scene acquired via linear pushbroom sensors. In this methodology, which is described in Section 6, no information concerning the relative or absolute orientation and path of the sensors with respect to each other is required. Using only ground control points, and without resorting to any iterative methods, one can determine the coordinates of 3D points corresponding to a set of matched image points.

One can question the assumptions underlying the linear pushbroom model when used for satellite imagery because the sensor array negotiates an elliptical trajectory and its look direction slowly rotates. However, if the segment of the orbit over which the image was acquired is small, it can be approximated by a straight line. For large orbital segments, one can solve the problem in a piece-wise linear manner. In a final section, the accuracy of the linear pushbroom model is discussed, and the results of some of the algorithms described here are given.

Experimental results confirm that the assumption about linearity is quite valid even for low-earth orbits and it does not have an adverse effect on the accuracy. For example, for SPOT images of size $6,000 \times 6,000$ pixels, covering an area about $60 \times 60 \text{ km}^2$, the linear and full models agree within less than half a pixel. This corresponds to a difference of about 6×10^{-6} radians, or about five meters on the ground. Section 7 also presents experimental results that compare the linear pushbroom model with a simple perspective camera, and an exact, orbiting pushbroom model that does not make any simplifying assumptions.

2 LINEAR PUSHBROOM SENSORS

In order to simplify the pushbroom camera model to facilitate computation and to provide a basis for theoretical investigation of the pushbroom model, certain simplifying assumptions can be made, as follows.

- The platform is moving in a straight line at constant velocity with respect to the world.
- The orientation of the camera, and hence the view plane, is constant.

This camera can be thought of as a perspective camera moving along a linear trajectory in space with constant velocity and fixed orientation (see Fig. 2). Furthermore, the camera is constrained so that at any moment in time it images only points lying in one plane, called the view plane, passing through the centre of the camera. Thus, at any moment of time, a 2D projection of the view plane onto an image line takes place. The orientation of the view plane is fixed, and it is assumed that the motion of the camera does not lie in the view plane. Consequently, the view plane sweeps out the whole of space as time varies between $-\infty$ and ∞ . The image of an arbitrary point \mathbf{x} in space is described by two coordinates. The first coordinate, u , represents the time when the point \mathbf{x} is imaged (that is, lies in the view plane) and the second

coordinate, v , represents the projection of the point on the image line.

We consider an orthogonal coordinate frame attached to the moving camera as follows (see Fig. 1). The origin of the coordinate system is the centre of projection. The y -axis lies in the view-plane parallel with the focal plane (in this case, the linear sensor array). The z -axis lies in the view plane perpendicular to the y -axis and directed so that the visible points have positive z coordinate. The x coordinate is perpendicular to the view plane such that x -, y -, and z -axes form a right-handed coordinate frame. The ambiguity of orientation of the y -axis in the above description can be resolved by requiring that the motion of the camera has a positive x component.

Fig. 2. Projection under linear pushbroom camera.

First of all, we consider a 2D projection. If the coordinates of a point are $(0, y, z)$ with respect to the camera frame, then the coordinate of this point in the 1D projection will be $v = fy/z + p_v$ where f is the focal length (or magnification) of the camera and p_v is the principal point offset in the v direction. This equation may be written in the form

$$\begin{pmatrix} wv \\ w \end{pmatrix} = \begin{pmatrix} f & p_v \\ 0 & 1 \end{pmatrix} \begin{pmatrix} y \\ z \end{pmatrix} \quad (1)$$

where w is a scale factor (actually equal to z).

Now for convenience, instead of considering a stationary world and a moving camera, it will be assumed that the camera is fixed and that the world is moving. A point in space will be represented as $\mathbf{x}(t) = (x(t), y(t), z(t))^T$ where t denotes time. Let the velocity vector of the points with respect to the camera frame be $-\mathbf{V} = -(V_x, V_y, V_z)^T$. The minus sign is chosen so that the velocity of the camera with respect to the world is \mathbf{V} . Suppose that a moving point in space crosses the view plane at time t_{im} at position $(0, y_{im}, z_{im})^T$. In the 2D pushbroom image, this point will be imaged at location (u, v) where $u = t_{im}$ and v may be expressed using (1). This may be expressed in an equation

$$\begin{pmatrix} u \\ wv \\ w \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & f & p_v \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} t_{im} \\ y_{im} \\ z_{im} \end{pmatrix} \quad (2)$$

Let \mathbf{x}_0 be the coordinates of a moving point \mathbf{x} at time $t = 0$. Since all points are moving with the same velocity, the coordinates of the point as a function of time, are given by the following equation.

$$\mathbf{x}(t) = \mathbf{x}_0 - t\mathbf{V} = (x_0, y_0, z_0)^T - t(V_x, V_y, V_z)^T \quad (3)$$

Since the view plane is the plane $x = 0$, the time t_{im} when the point \mathbf{x} crosses the view plane is given by $t_{im} = x_0/V_x$. At that moment, the point will be at position

$$(0, y_{im}, z_{im})^T = (0, y_0 - x_0 V_y/V_x, z_0 - x_0 V_z/V_x)^T.$$

We may write this as

$$\begin{pmatrix} t_{im} \\ y_{im} \\ z_{im} \end{pmatrix} = \begin{pmatrix} 1/V_x & 0 & 0 \\ -V_y/V_x & 1 & 0 \\ -V_z/V_x & 0 & 1 \end{pmatrix} \begin{pmatrix} x_0 \\ y_0 \\ z_0 \end{pmatrix} \quad (4)$$

Combining this with (2) gives the equation

$$\begin{pmatrix} u \\ wv \\ w \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & f & p_v \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1/V_x & 0 & 0 \\ -V_y/V_x & 1 & 0 \\ -V_z/V_x & 0 & 1 \end{pmatrix} \begin{pmatrix} x_0 \\ y_0 \\ z_0 \end{pmatrix} \quad (5)$$

In these equations, $(x_0, y_0, z_0)^T$ are the coordinates of the point \mathbf{x} in terms of the camera frame at time $t = 0$. Normally, however, the coordinates of a point are known not in terms of the camera-based coordinate system, but rather in terms of some fixed external orthogonal coordinate system. In particular, let the coordinates of the point in such a coordinate system be $(x, y, z)^T$. Since both coordinate frames are orthogonal, the coordinates are related via a transformation

$$\begin{aligned} (x_0, y_0, z_0)^T &= R \left((x, y, z)^T - (T_x, T_y, T_z)^T \right) \\ &= (R| - R\mathbf{T}) (x, y, z, 1)^T \end{aligned} \quad (6)$$

where $\mathbf{T} = (T_x, T_y, T_z)^T$ is the location of the camera at time $t = 0$ in the external coordinate frame, and R is a rotation matrix.

Finally, putting this together with (5) leads to

$$\begin{aligned} \begin{pmatrix} u \\ wv \\ w \end{pmatrix} &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & f & p_v \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1/V_x & 0 & 0 \\ -V_y/V_x & 1 & 0 \\ -V_z/V_x & 0 & 1 \end{pmatrix} (R| - R\mathbf{T}) \begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} \\ &= M(x, y, z, 1)^T \end{aligned} \quad (7)$$

Equation (7) should be compared with the basic equation describing pinhole, or perspective cameras, namely, $(u, wv, w)^T = M(x, y, z, 1)^T$ where $(x, y, z)^T$ are the coordinates of a world point, $(u, v)^T$ are the coordinates of the corresponding image point and w is a scale factor. It may be seen that a linear pushbroom image may be thought of as a projective image in one direction (the v direction) and an or-

thographic image in the other direction (the u direction).

An important difference must be noted between the camera matrix of a perspective camera and the matrix M of a linear pushbroom mapping. A perspective camera matrix is a homogeneous quantity, meaning that two such matrices that differ by a nonzero constant scale factor encode the same mapping, and are thought of as being equivalent. On the other hand, the linear pushbroom camera matrix is *not* a homogeneous quantity. Examination of the basic equation $(u, wv, w)^T = M\mathbf{x}$ reveals that since multiplication of the matrix M by a constant factor k results in multiplying the u coordinate of the image point by k . The v coordinate, on the other hand, is unchanged. In fact, the last two rows of M may be multiplied by a factor k without changing the mapping. A count of degrees of freedom shows that the first row of M has four degrees of freedom, whereas the other two rows account for seven degrees of freedom, since they are scale insensitive. The linear-pushbroom mapping has 11 degrees of freedom in all.

The camera matrix M in (7) for a linear pushbroom sensor can model translation, rotation, and scaling of the 3D world coordinates as well as translation and scaling of 2D image coordinates. However, it cannot account for rotation in the image plane. In general, a 2D perspective transform of an image taken by a linear pushbroom camera cannot be thought of as another image taken by different linear pushbroom camera. Many resampling operation—e.g., resampling images in a stereo pair so that the match point disparities are only along one of the image coordinates [6]—cannot be performed on linear pushbroom imagery without breaking the mapping encoded in (7).

2.1 Points in Front of the Camera

Recall that the camera coordinate frame was set up in such a way that the positive z -axis was directed so that visible points had positive z coordinated. Referring to (1), we see that visible points are mapped to points for which $w > 0$. This property is preserved through a change of world coordinates. Thus, referring to (7), one sees that if the point $\mathbf{x} = (x, y, z, 1)^T$ is in front of the camera, then $(u, wv, w)^T = M\mathbf{x}$ with $w > 0$, and M defined as in (7).

We have seen that the image point defined by $M\mathbf{x}$ is unchanged if the last two rows of M are multiplied by a constant factor, k . However, if this constant factor k is negative, then w changes sign. This does not change the value of the projected point, but it does affect the determination of which points are in front of the camera and which are behind. Thus, if we wish to preserve this information, then we may allow multiplication of the last two columns of M by a positive constant only. We may summarize the findings of this section as follows:

PROPOSITION 1. *The linear pushbroom mapping may be encoded in a 3×4 matrix M , which determines the mapping $(u, wv, w)^T = M(x, y, z, 1)^T$, where $(x, y, z)^T$ are the coordinates of a 3D world point, and (u, v) are the corresponding 2D image coordinates. The point $(x, y, z)^T$ lies in front of the camera and is potentially visible if and only if $w > 0$. The matrix M is defined by these conditions up to multiplication of the last two rows by a positive scalar constant k .*

3 DETERMINATION OF THE CAMERA MATRIX

In this section it will be shown how a linear pushbroom camera matrix may be computed given a set of ground control points. The method is an adaptation of the Direct Linear Transformation (DLT) method [7] used for the pinhole cameras. In particular, denoting by \mathbf{m}_1^\top , \mathbf{m}_2^\top , and \mathbf{m}_3^\top the three rows of the matrix M and $\mathbf{x} = (x, y, z, 1)^\top$ a ground control point, (7) may be written in the form of three equations

$$\begin{aligned} u &= \mathbf{m}_1^\top \mathbf{x} \\ wv &= \mathbf{m}_2^\top \mathbf{x} \\ w &= \mathbf{m}_3^\top \mathbf{x} \end{aligned} \quad (8)$$

The unknown factor w can be eliminated, leading to two equations

$$\begin{aligned} u &= \mathbf{m}_1^\top \mathbf{x} \\ v\mathbf{m}_3^\top \mathbf{x} &= \mathbf{m}_2^\top \mathbf{x} \end{aligned} \quad (9)$$

Supposing that the world coordinates (x, y, z) and image coordinates (u, v) are known, (9) are a set of linear equations in the unknown entries of the matrix M . Given sufficiently many ground control points we can solve for the matrix M .

One solves for the first row of M independently of the last two rows. In particular, note that the entries in the row \mathbf{m}_1^\top rely only on the u coordinates of the ground control points. Given four ground control points one obtains a nonhomogeneous set of equations in the entries of \mathbf{m}_1^\top , from which one may solve for the first row of M . With more than four points, a least-squares solution is computed.

Similarly, the second and third rows of M depend only on the v coordinates of the matrix. Given seven ground control points, one obtains a homogeneous set of equations in the entries of \mathbf{m}_2^\top and \mathbf{m}_3^\top . These equations may be solved to find the second and third rows of M . Once more a least-squares solution is found when more than seven matches are given. The solution of the nonhomogeneous set of equations is the singular vector corresponding to the least singular value of the equation matrix [8].

The last two rows of M are determined by this method only up to an unknown constant factor. To determine the matrix M that correctly determines which points are in front of the camera, according to Proposition 1 one proceeds as follows. One of the ground control points \mathbf{x}_i is chosen and the product $(u_i, w_i v_i, w_i)^\top = M\mathbf{x}_i$ is computed. If $w_i < 0$, then the last two rows of M are multiplied by -1 . In this way, one obtains a matrix satisfying Proposition 1. If the data is correct, then all points should be in front of the camera, so this procedure does not depend on which of the points \mathbf{x}_i is chosen.

3.1 Mapping of Lines Under M

In order to see the nonlinear nature of the mapping func-

tion performed by M , it is instructive to see how lines in space are mapped in the image plane by M . A linear pushbroom transforms a point \mathbf{x} in to u and v according to (9). Constraining \mathbf{x} to lie on a line in 3-D is given by $V_p + tV_a$, where V_p is a point on the line, and V_a is a vector along the line, the image of this line under M is given by

$$u = \mathbf{m}_1^\top (V_p + tV_a) \quad (10)$$

$$v = \frac{\mathbf{m}_2^\top (V_p + tV_a)}{\mathbf{m}_3^\top (V_p + tV_a)} \quad (11)$$

Eliminating t from these equations, one gets an equation of the form $\alpha u + \beta v + \gamma uv + \delta = 0$, which is the equation of a hyperbola in the image plane.

4 PARAMETER RETRIEVAL

As already remarked, the last two rows of matrix M may be multiplied by a constant without affecting the relationship between world point coordinates (x, y, z) and image coordinates (u, v) expressed by (7). This means that the 3×4 matrix M contains only 11 degrees of freedom. On the other hand, it may be verified that the formation of a linear pushbroom image is also described by 11 parameters, namely, the position (3) and orientation (3) of the camera at time $t = 0$, the velocity of the camera (3) and the focal length and v-offset (2). It will next be shown how the linear pushbroom parameters may be computed given the matrix M . This comes down to finding a factorization of M of the kind given in (7). The corresponding problem for pinhole cameras has been solved by Ganapathy [9] and Strat [10], but is more easily done by in a manner similar to that used below, a variation on the standard QR factorization method [11].

The purpose of determining the individual camera parameters, rather than just using the projection matrix M is to allow knowledge of the camera parameters to influence the calibration of the camera. For instance, the focal length and principal point offset of the camera may be known quite precisely from manufacturing specifications. In the DLT method for determining the camera matrix M , as described in Section 3, there is no way to incorporate this information into the calibration process. One way in which this may be done, however, is to get an initial solution for the camera matrix M , extract the parameters from the matrix in the manner to be described in this section, fix the known parameters to known values, and finally carry out an iterative parameter fitting algorithm to get a more exact estimate of the camera mapping. Our camera modeling program Carmen [12] uses this approach, allowing any of the parameters to be fixed absolutely, or with a specified standard deviation. It is possible to parametrize the camera in different ways to allow for different types of knowledge of the camera setup.

To determine the camera parameters, first of all we determine the position of the camera at time $t = 0$, referred to subsequently as the initial position of the camera. Multiplying out the product (7), it may be seen that M is of the form $(K | -KT)$ for a nonsingular 3×3 matrix K . Therefore,

it is easy to solve for \mathbf{T} by solving the linear equations $\mathbf{KT} = -\mathbf{m}^4$ where \mathbf{m}^4 is the last column of \mathbf{M} , and \mathbf{K} is the left-hand 3×3 block.

Next, we consider the matrix \mathbf{K} . According to (7), and bearing in mind that the two bottom rows of \mathbf{K} may be multiplied by a constant positive factor k , matrix \mathbf{K} is of the form

$$\mathbf{K} = \begin{pmatrix} 1/V_x & 0 & 0 \\ -k(fV_y + p_v V_z)/V_x & kf & kp_v \\ -kV_z/V_x & 0 & k \end{pmatrix} \mathbf{R} = \mathbf{L}\mathbf{R} \quad (12)$$

where \mathbf{R} is a rotation matrix. We are given \mathbf{K} , and desire to compute \mathbf{L} . In order to find this factorization, we multiply \mathbf{K} on the right by a sequence of Givens rotation matrices to reduce it to the form taken by \mathbf{L} in (12). A 3×3 Givens rotation is a matrix of the form

$$\mathbf{R}_x = \begin{pmatrix} 1 & & \\ & c & -s \\ & s & c \end{pmatrix}; \mathbf{R}_y = \begin{pmatrix} c & & s \\ & 1 & \\ -s & & c \end{pmatrix} \text{ or } \mathbf{R}_z = \begin{pmatrix} c & -s & \\ s & c & \\ & & 1 \end{pmatrix} \quad (13)$$

where $c = \cos(\theta)$ and $s = \sin(\theta)$ for some angle θ chosen to eliminate some element of the camera matrix. In the present case, the necessary rotations will be successive Givens rotations \mathbf{R}_z , \mathbf{R}_y , and \mathbf{R}_x with angles chosen to eliminate the (1,2), (1,3), and (3,2) entries of \mathbf{K} . For instance, the first rotation will be \mathbf{R}_z where

$$\cos(\theta_z) = k_{11} / (k_{11}^2 + k_{12}^2)^{1/2}$$

and

$$\sin(\theta_z) = k_{12} / (k_{11}^2 + k_{12}^2)^{1/2}.$$

Subsequent rotation angles are chosen in a similar manner. In this way, we find a factorization of \mathbf{K} as a product $\mathbf{K} = \mathbf{L}\mathbf{R}$ where \mathbf{R} is a rotation matrix and \mathbf{L} is a matrix having zeros in the required positions. This factorization is similar to the \mathbf{QR} factorization of matrices [11].

At this point, one may find that one or both of the entries L_{22} and L_{33} are negative. This would contradict our requirement that $L_{33} = k > 0$, or the geometrically imposed requirement that the focal length $L_{22}/L_{33} = f > 0$. One may correct this as follow. If $L_{33} > 0$, then one applies a further rotation \mathbf{R}_y through an angle π about the y axis. Such a rotation has a diagonal rotation matrix (13) equal to $\text{diag}(-1, 1, -1)$. If in addition, $L_{22} < 0$, then one applies a further rotation \mathbf{R}_z through angle π about the z axis. This rotation has matrix $\text{diag}(-1, -1, 1)$. The matrix so obtained, defined by the condition $\mathbf{K} = \mathbf{L}\mathbf{R}$ with L_{22} and L_{33} positive is uniquely determined.

Now, equating \mathbf{L} with the left hand matrix in (12), it is seen that the parameters f , p_v , V_x , V_y and V_z may easily be read from the matrix \mathbf{L} . In particular, we can immediately read the value $k = L_{33}$. Next the last two rows of \mathbf{L} are multiplied by the factor k^{-1} so that $L_{33} = 1$. Then

$$\begin{aligned} f &= L_{22} \\ p_v &= L_{23} \\ V_x &= 1 / L_{11} \\ V_z &= -L_{31} / L_{11} \\ V_y &= \frac{-(L_{21} - p_v L_{31})}{f L_{11}} \end{aligned}$$

In summary:

PROPOSITION 2. *The 11 parameters of a linear pushbroom camera are uniquely determined and may be computed from the 3×4 camera matrix defined by the requirements of Proposition 1.*

It is worth noting that without the information about the front and back of the camera, the parameters are not uniquely determined. The specification of the front of the camera allows us to determine the camera matrix up to multiplication of the last two rows by a constant positive factor. Without this specification, they are known only up to a constant factor, positive or negative. In this case, applying a rotation $\mathbf{R}_x(\pi)$ with matrix $\text{diag}(1, -1, -1)$ will change the sign of the last two columns of \mathbf{L} , including the value of $L_{33} = k$. Then following the procedure above for determining the parameters will lead to values of V_y and V_z with opposite sign. Note that this rotation through π about the x axis corresponds to flipping the camera upside down by rotation about an axis perpendicular to the instantaneous view plane.

5 RELATIVE CAMERA MODEL DETERMINATION

The problem of determining the relative camera placement of two or more pinhole cameras and consequent determination of pinhole cameras has been extensively considered. Most relevant to the present paper is the work of Longuet-Higgins [2], who introduced the so-called essential matrix \mathbf{F} . If $\{(\mathbf{u}_i, \mathbf{u}'_i)\}$ is a set of match points in a stereo pair, \mathbf{F} is defined by the relation $\mathbf{u}_i^T \mathbf{F} \mathbf{u}_i = 0$ for all i . As shown in [3], $(r, s, t)^T = \mathbf{F} \mathbf{u}_i$ is the equation of the epipolar line corresponding to \mathbf{u}_i in the second image. (The line $(r, s, t)^T$ in homogeneous coordinates corresponds to the line equation $ru + sv + t = 0$, in the image-space.) \mathbf{F} may be determined from eight or more correspondence points between two images by linear techniques.

Other nonlinear techniques for determining \mathbf{F} , more stable in the presence of noise, have been published [13], [14], [15], [16]. Those techniques relate especially to so-called calibrated cameras, for which the internal parameters are known. Some papers that deal with the determination of the fundamental matrix for uncalibrated cameras are [17], [18]. As for the determination of the world coordinates of points see from two pinhole cameras, it has been shown [5], [4] that for uncalibrated cameras the position of world points is determined up to an unknown projective transform by their images in two separate views.

Similar results for linear pushbroom cameras will be shown here. In Section 5.1, the *LP fundamental matrix* for linear pushbroom cameras, which is analogous to the fundamental matrix for pinhole cameras, is introduced. The epipolar geometry of linear pushbroom cameras is discussed in Section 5.2. In Section 5.3, we prove that an LP fundamental matrix, which encodes the relative orientation of two linear pushbroom cameras, determines the 3D points in object space up to an affine transformation of space. Thus the knowledge of relative orientation in the case of linear pushbrooms is more constraining than that for perspective

cameras; in the later case the ambiguity is a projective transformation of space. Sections 5.4 and 5.5 are devoted to a discussion of the critical sets and computation of F from a set of matched points.

5.1 Definition of the LP Fundamental Matrix

Consider a point $\mathbf{x} = (x, y, z)^\top$ in space as viewed by two linear pushbroom cameras with camera matrices M and M' . Let the images of the two points be $\mathbf{u} = (u, v)^\top$ and $\mathbf{u}' = (u', v')^\top$. This gives a pair of equations

$$\begin{aligned} (u, v, w)^\top &= M(x, y, z, 1)^\top \\ (u', v', w')^\top &= M'(x, y, z, 1)^\top \end{aligned} \quad (14)$$

This pair of equations may be written in a different form as

$$\begin{pmatrix} m_{11} & m_{12} & m_{13} & m_{14} - u & 0 & 0 \\ m_{21} & m_{22} & m_{23} & m_{24} & v & 0 \\ m_{31} & m_{32} & m_{33} & m_{34} & 1 & 0 \\ m'_{11} & m'_{12} & m'_{13} & m'_{14} - u' & 0 & 0 \\ m'_{21} & m'_{22} & m'_{23} & m'_{24} & 0 & v' \\ m'_{31} & m'_{32} & m'_{33} & m'_{34} & 0 & 0 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \\ 1 \\ -w \\ -w' \end{pmatrix} = 0 \quad (15)$$

The 6×6 matrix in (15) will be denoted $A(M, M')$. Considered as a set of linear equations in the variables x, y, z, w , and w' and constant one, this is a set of six homogeneous equations in six unknowns (imagining one to be an unknown). If this system is to have a solution, then $\det A(M, M') = 0$. This condition gives rise to a cubic equation $p(u, v, u', v') = 0$ where the coefficients of p are determined by the entries of M and M' . The polynomial p will be called the *fundamental polynomial* corresponding to the two cameras. Because of the particular form of (15) there are no terms in u^2, u'^2, v^2 , or v'^2 in the fundamental polynomial. Consequently, there exists a 4×4 matrix F such that $p(u, v, u', v') = 0$ may be written:

$$(u', u'v', v', 1) F(u, uv, v, 1)^\top = 0 \quad (16)$$

The matrix F will be called the *LP fundamental matrix* corresponding to the linear pushbroom camera pair $\{M, M'\}$. Matrix F is just a convenient way to display the coefficients of the fundamental polynomial. Since the entries of F depend only on the two camera matrices, M and M' , (16) must be satisfied by any pair of corresponding image points (u, v) and (u', v') . The same basic proof method used above may be used to prove the existence of the fundamental matrix for pinhole cameras [19].

It is seen that if either M or M' is replaced by an equivalent matrix by multiplying the last two rows by a constant c , then the effect is to multiply $\det A(M, M')$, and hence the fundamental polynomial p and matrix F by the same constant c (not c^2 as may appear at first sight). Consequently, two fundamental polynomial or matrices that differ by a constant nonzero factor will be considered equivalent. Thus, unlike the camera matrices M and M' , the LP fundamental matrix F is a homogeneous object, defined only up to nonzero scale.

A closer examination of the matrix $A(M, M')$ in (15) reveals that $p = \det A(M, M')$ contains no terms in uu', uvu' ,

$uu'v'$, or $uvu'v'$. In other words, the top left-hand 2×2 sub-matrix of F is zero. This is formally stated below.

THEOREM 3. Let $\mathbf{u}_i = (u_i, v_i, 1)^\top$ and $\mathbf{u}'_i = (u'_i, v'_i, 1)^\top$ be the image coordinates of 3D points p_i ($i = 1, \dots, n$) under two linear pushbroom cameras. For all i , there exists a matrix $F = (f_{ij})$, such that

$$\begin{pmatrix} u'_i & u'_i v'_i & v'_i & 1 \end{pmatrix} \begin{pmatrix} 0 & 0 & f_{13} & f_{14} \\ 0 & 0 & f_{23} & f_{24} \\ f_{31} & f_{32} & f_{33} & f_{34} \\ f_{41} & f_{42} & f_{43} & f_{44} \end{pmatrix} \begin{pmatrix} u_i \\ u_i v_i \\ v_i \\ 1 \end{pmatrix} = 0 \quad (17)$$

Since F is defined only up to a constant factor, it contains no more than 11 degrees of freedom. Given a set of 11 or more image-to-image correspondences the matrix F can be determined by the solution of a set of linear equations just as with pinhole cameras.

5.2 Epipolar Geometry

One of the most striking differences between linear pushbroom and perspective cameras is the epipolar geometry. First of all there are no epipoles in the familiar manner of perspective cameras, since the two pushbroom cameras are moving with respect to each other. Neither is it true that epipolar lines are straight lines.

Consider a pair of matched point $(u, v)^\top$ and $(u', v')^\top$ in two images. According to (16), these points satisfy $(u', u'v', v', 1) F(u, uv, v, 1)^\top = 0$. Now, fixing $(u, v)^\top$ and inquiring for the locus of all possible matched points $(u', v')^\top$, and writing $(\alpha, \beta, \gamma, \delta)^\top = F(u, uv, v, 1)^\top$, we see that $\alpha u' + \beta u'v' + \gamma v' + \delta = 0$. This is the equation of a hyperbola—epipolar loci are hyperbolas for linear pushbroom cameras. F can be used in match point computation to enforce the epipolar constraint.

The epipolar locus of a point is the projection in the second image of a straight line emanating from the instantaneous centre of projection of the first camera. Hyperbolic epipolar curves are expected because, as already proved, under the linear pushbroom model lines in space map into hyperbolas in the image plane. Only one of the two branches of the hyperbola will be visible in the image. The other branch will lie behind the camera.

The LP fundamental matrix contains all the information about relative camera parameters for completely *uncalibrated* linear pushbroom cameras (that is, cameras about which nothing is known) that can be derived from a set of match points. In the following section, we consider the information that can be extracted from F .

5.3 Extraction of Relative Cameras From F

Longuet-Higgins [2] showed that for calibrated cameras the relative position and orientation of the two cameras may be deduced from the fundamental matrix. This result was extended to uncalibrated cameras in [4], [5], where it was shown that if M_1 and M'_1 are one pair of cameras corresponding to a fundamental matrix F and if M_2 and M'_2 are another pair corresponding to the same fundamental matrix, then there is a 4×4 matrix H such that $M_1 = M_2 H$ and $M'_1 = M'_2 H$. This result will be shown to hold for linear pushbroom cameras with the restriction that H must be a matrix representing an affine transformation, that is, the

last row of H is $(0, 0, 0, 1)$.

First of all, it will be shown that M and M' may be multiplied by an arbitrary affine transformation matrix without changing the LP fundamental matrix. Let H be a 4×4 affine transformation matrix and let \bar{H} be the 6×6 matrix

$$\bar{H} = \begin{pmatrix} H & 0 \\ 0 & I \end{pmatrix}$$

where I is the 2×2 identity matrix. If A is the matrix in (15) it may be verified with a little work that

$$A(M, M')\bar{H} = A(MH, M'H),$$

where the assumption that the last row of H is $(0, 0, 0, 1)$ is necessary. Therefore,

$$\det A(MH, M'H) = \det A(M, M') \det H$$

and so the fundamental polynomials corresponding to pairs $\{M, M'\}$ and $\{MH, M'H\}$ differ by a constant factor and so are equivalent.

The same result may be proven in a more intuitive fashion as follows. The LP fundamental matrix depends only on the image coordinates of the matched points. Therefore, investigate which transformations may be carried out on the cameras and 3D spatial points without altering the image coordinates. One observes that if M is replaced by MH^{-1} and each point \mathbf{x}_i is replaced by $H\mathbf{x}_i$, then $(u_i, v_i, w_i)^T = M\mathbf{x}_i = (MH^{-1})(H\mathbf{x}_i)$. Thus the image coordinates, and hence the fundamental matrix are unchanged by this affine transformation of the 3D points. The same argument is used in the case of pinhole cameras, but in that case, H may be any projective transformation, and so reconstruction is possible only up to a projective transformation. It is instructive to see why this is not possible in the present case of linear pushbroom cameras.

For an arbitrary projective transformation, H , we see that

$$H\mathbf{x}_i = H(x_i, y_i, z_i, 1)^T = (x'_i, y'_i, z'_i, t'_i)^T,$$

where t'_i is generally not equal to one. However, in Proposition 1, defining the LP camera mapping, the 3D point must be written in the form $(x, y, z, 1)^T$ with unit last coordinate. To achieve this, we divide by t'_i , which leads to

$$(MH^{-1})(x'_i / t'_i, y'_i / t'_i, z'_i / t'_i, 1)^T = (u_i / t_i, v_i / t_i, w_i / t_i)^T.$$

This last vector represents the 2D image point $(u'_i / t'_i, v'_i / t'_i)^T$ which is not the same as the original point $(u_i, v_i)^T$. Thus, the proposed projective transformation does not keep the image points fixed. On the other hand, if H is an affine transformation, then the last row of H is $(0, 0, 0, 1)$, and one sees that $H(x_i, y_i, z_i, 1)^T = (x'_i, y'_i, z'_i, 1)^T$. That is, the last coordinate is always one, and the problem does not occur.

These results suggest that the two camera matrices should be determined up to affine transformation from the LP fundamental matrix. It will now be shown that this is indeed true, and a constructive procedure will be given for computing them. It has just been demonstrated that the camera matrices and 3D points may be multiplied by an

arbitrary 4×4 affine matrix H and its inverse without affecting the LP fundamental matrix, or the 2D image points. Therefore, we may choose to set the matrix M' to a particularly simple form $(I | 0)$ where I is an identity matrix. Indeed, let $M' = (R | \mathbf{t})$. We can transform M' to $(I | 0)$ by post multiplying both M and M' by the affine matrix

$$\begin{pmatrix} R^{-1} & -R^{-1}\mathbf{t} \\ 0 & 1 \end{pmatrix}$$

It will be seen that with the assumption that $M' = (I | 0)$, the other matrix M is almost uniquely determined by the LP fundamental matrix.

Under the assumption that $M' = (I | 0)$, F may be computed explicitly in terms of the entries of M . Using Mathematica [20] or by hand, it may be computed that

$$F = (f_{ij}) = \begin{pmatrix} 0 & 0 & (m_{11}m_{33} - m_{13}m_{31}) & (m_{13}m_{21} - m_{11}m_{23}) \\ 0 & 0 & (m_{11}m_{32} - m_{12}m_{31}) & (m_{12}m_{21} - m_{11}m_{22}) \\ m_{22} & -m_{32} & (m_{14}m_{32} - m_{12}m_{34}) & (m_{12}m_{24} - m_{14}m_{22}) \\ m_{23} & -m_{33} & (m_{14}m_{33} - m_{13}m_{34}) & (m_{13}m_{24} - m_{14}m_{23}) \end{pmatrix} \quad (18)$$

Given the entries f_{ij} of F the question is whether it is possible to retrieve the values of the entries m_{ij} . This involves the solution of a set of 12 equations in the 12 unknown values m_{ij} . The four entries m_{22} , m_{23} , m_{32} , and m_{33} may be immediately obtained from the bottom left hand block of F . In particular,

$$\begin{aligned} m_{22} &= f_{31} \\ m_{23} &= f_{41} \\ m_{32} &= -f_{32} \\ m_{33} &= -f_{42} \end{aligned} \quad (19)$$

Retrieval of the remaining entries is more tricky but may be accomplished as follows. The four nonzero entries in the first two rows can be rewritten in the following form (using (19) to substitute for m_{22} , m_{23} , m_{32} , and m_{33}).

$$\begin{pmatrix} -f_{42} & 0 & -m_{13} & -f_{13} \\ -f_{41} & m_{13} & 0 & -f_{14} \\ -f_{32} & 0 & -m_{12} & -f_{23} \\ -f_{31} & m_{12} & 0 & -f_{24} \end{pmatrix} \begin{pmatrix} m_{11} \\ m_{21} \\ m_{31} \\ 1 \end{pmatrix} = 0 \quad (20)$$

Similarly, the bottom right hand 2×2 block gives a set of equations

$$\begin{pmatrix} -f_{42} & 0 & -m_{13} & -f_{43} \\ -f_{41} & m_{13} & 0 & -f_{44} \\ -f_{32} & 0 & -m_{12} & -f_{33} \\ -f_{31} & m_{12} & 0 & -f_{34} \end{pmatrix} \begin{pmatrix} m_{14} \\ m_{24} \\ m_{34} \\ 1 \end{pmatrix} = 0 \quad (21)$$

Immediately it can be seen that if we have a solution m_{ij} , then a new solution may be obtained by multiplying m_{12} and m_{13} by any nonzero constant c and dividing m_{21} , m_{31} , m_{24} , and m_{34} by the same constant c . In other words, unless $m_{13} = 0$, which may easily be checked, we may assume that $m_{13} = 1$. From the assumption of a solution to (20) and (21)

may be deduced that the 4×4 matrices in (20) and (21) must both have zero determinant. With $m_{13} = 1$, each of (20) and (21) gives a quadratic equation in m_{12} . In order for a solution to exist for the sought matrix M , these two quadratics must have a common root. This condition is a necessary condition for a matrix to be an LP fundamental matrix. Rearranging the matrices slightly, writing λ instead of m_{12} and expressing the existence of a common root in terms of the resultant leads to the following statement.

THEOREM 4. *If a matrix 4×4 matrix $F = (f_{ij})$ is an LP fundamental matrix, then*

- 1) $f_{11} = f_{12} = f_{21} = f_{22} = 0$

- 2) *the resultant of the polynomials*

$$\det \begin{pmatrix} \lambda & 0 & f_{31} & f_{24} \\ 0 & \lambda & f_{32} & f_{23} \\ 1 & 0 & f_{41} & f_{14} \\ 0 & 1 & f_{42} & f_{13} \end{pmatrix} \quad (22)$$

and

$$\det \begin{pmatrix} \lambda & 0 & f_{31} & f_{34} \\ 0 & \lambda & f_{32} & f_{33} \\ 1 & 0 & f_{41} & f_{44} \\ 0 & 1 & f_{42} & f_{43} \end{pmatrix} \quad (23)$$

vanishes.

- 3) *The discriminants of the polynomials (22) and (23) are both nonnegative.*

If the two quadratics have a common root, then this common root will be the value of m_{12} . The linear equations (20) may then be solved for m_{11} , m_{21} , and m_{31} . Similarly, (21) may be solved for m_{14} , m_{24} , and m_{34} . Unless $f_{31}f_{42} - f_{41}f_{32}$ vanishes, the first three columns of the matrices (20) and (21) will be linearly independent, and the solutions for the m_{ij} will exist and be unique.

To recapitulate, if m_{12} is a common root of the two quadratic polynomials (22) and (23), m_{13} is chosen to equal one, and $f_{31}f_{42} - f_{41}f_{32} \neq 0$, then the matrix $M = (m_{ij})$ may be uniquely determined by the solution of a set of linear equations. Relaxing the condition $m_{13} = 1$ leads to a family of solutions of the form

$$\begin{pmatrix} m_{11} & m_{12}c & m_{13}c & m_{14} \\ m_{21}/c & m_{22} & m_{23} & m_{24}/c \\ m_{31}/c & m_{32} & m_{33} & m_{34}/c \end{pmatrix} \quad (24)$$

However, up to multiplication by the diagonal affine matrix $\text{diag}(1, 1/c, 1/c, 1)$, all such matrices are equivalent. Furthermore, the matrix $M' = (I | 0)$ is mapped unto an equivalent matrix by multiplication by $\text{diag}(1, 1/c, 1/c, 1)$. This shows that once m_{12} is determined, the matrix pair $\{M, M'\}$ may be computed uniquely up to affine equivalence.

Finally, we consider the possibility that (22) and (23) have two common roots. This can only occur if the coefficients of F satisfy certain restrictive identities that may be deduced from (22) and (23). This allows us to state:

THEOREM 5. *Given a 4×4 matrix F satisfying the conditions of Proposition 4, the pair of camera matrices $\{M, M'\}$ corresponding to F is uniquely determined up to affine equivalence, unless F lies in a lower dimensional critical set.*

The complete algorithm for computing the camera matrices (up to an affine transformation) from the LP fundamental matrix is now summarized.

- 1) Set $M' = (I | 0)$.
- 2) Set $m_{22} = f_{31}$, $m_{23} = f_{41}$, $m_{32} = -f_{32}$, $m_{33} = -f_{42}$.
- 3) Set $m_{13} = 1$ and set $\lambda = m_{12}$ to be the common root of the determinants (22) and (23).
- 4) Solve (20) and (21) to find the remaining entries of M .

5.4 More About the Critical Set

It is not the purpose here to undertake a complete investigation of the critical set. As previously stated, conditions under which there are two common roots to (22) and (23) leading to two distinct solutions for M may be deduced from the form of (22) and (23). This investigation will give a condition in terms of the entries of F . More enlightening would be a conditions in terms of the entries of the matrix M for the solution to be ambiguous. This will be investigated next.

There will be ambiguous solutions to the problem of estimating the matrix M if the polynomials (22) and (23) have two common roots. Suppose that the matrix F is of the form given in (18). Then we may compute the two quadratic polynomials from (22) and (23). The results (computed using Mathematica) are

$$p_1(\lambda) = (m_{13}\lambda - m_{12}) (m_{22}m_{31} - m_{21}m_{32} - \lambda(m_{23}m_{31} - m_{21}m_{33}))$$

$$p_2(\lambda) = (m_{13}\lambda - m_{12}) (m_{22}m_{34} - m_{24}m_{32} - \lambda(m_{23}m_{34} - m_{24}m_{33}))$$

As expected, $p_1(\lambda)$ and $p_2(\lambda)$ have a common root $\lambda = m_{12}/m_{13}$. The second root of p_1 and p_2 is the same if and only if the two linear polynomials

$$(m_{22}m_{31} - m_{21}m_{32} - \lambda(m_{23}m_{31} - m_{21}m_{33}))$$

and

$$(m_{22}m_{34} - m_{24}m_{32} - \lambda(m_{23}m_{34} - m_{24}m_{33}))$$

have the same root. Computation reveals that this is so if and only if

$$(m_{21}m_{34} - m_{24}m_{31}) (m_{22}m_{33} - m_{23}m_{32}) = 0 \quad (25)$$

Since the right-hand side of this expression is a product of two factors, there are two separate conditions under which an ambiguous solution may exist. The first condition $(m_{21}m_{34} - m_{24}m_{31}) = 0$ corresponds geometrically to the situation where the trajectories of the two cameras meet in space. This may be seen as follows. A point $\mathbf{x} = (x, y, z)^T$ lies on the trajectory of the centre of projection of a camera with matrix M if and only if $M(x, y, z, 1)^T = (u, 0, 0)^T$, for under these circumstances the v coordinate of the image is undefined. In particular, the points that lie on the trajectory of the camera M' with matrix $(I|0)$ are of the form $(x, 0, 0)^T$. Such a point will also lie on the trajectory of the camera

with matrix M if and only if $xm_{21} + m_{24} = xm_{31} + m_{34} = 0$ for some x ; that is, if and only if $m_{21}m_{34} - m_{24}m_{31} = 0$.

One may verify that in this case, there are in fact two distinct solutions. The geometric condition is that the two trajectories meet. For simplicity, we suppose that the two trajectories meet at the origin of the coordinate system at time $t = 0$. In this case, one may assume that the two camera matrices are $(I|0)$ and $M = (K|0)$. Let $k_{ij}^* = \det \bar{K}_{ij}$, where \bar{K}_{ij} is the matrix obtained from K by eliminating the i th row and j th column. Further, let the entries of K be k_{ij} . Define a matrix K_2 by the expression

$$K_2 = \begin{pmatrix} \det(K) / k_{11}^* & k_{13}^* & k_{12}^* \\ -k_{31}^* / k_{11}^* & k_{22} & k_{23} \\ -k_{21}^* / k_{11}^* & k_{32} & k_{33} \end{pmatrix}$$

Then it may be verified (using Mathematica, for instance) that the pair $(I|0)$, $(K_2|0)$ has the same LP fundamental matrix, defined by (18) as the pair $(I|0)$, $(K|0)$.

It may be shown that the second condition corresponds geometrically to the trajectory of camera M being parallel to the view plane of camera M' . However, a proof of this is omitted, since in fact, this condition does not lead to a second solution. The condition $m_{22}m_{33} - m_{23}m_{32} = 0$ is equivalent (see (18)) to the condition that $q_{31}q_{42} - q_{41}q_{32} = 0$. It turns out that in this case, the matrices in (20) and (21) have rank three, but their null-spaces are of the form $(a, b, c, 0)$. Hence, the corresponding sets of equations do not admit a solution with final entry equal to one, as required.

5.5 Computation of the LP Fundamental Matrix

The matrix F may be computed from image correspondences in much the same way as Longuet-Higgins computes the perspective fundamental matrix [2]. Given 11 or more point-to-point correspondences between a pair of linear pushbroom images, (16) can be used to solve for the 12 nonzero entries of F , up to multiplication by an unknown scale. It is important in implementing this linear algorithm that the image correspondence data is normalized in the way described in [18]. Unfortunately, in the presence of noise, the solution found in this way for F will not satisfy the second condition of (4) exactly. Consequently, when solving for the matrix M , one will find that the two polynomials (22) and (23) do not have a common root. Various strategies are possible at this stage.

One strategy is as follows. Consider each of the two roots m_{12} of (22) and with each such value of m_{12} proceed as follows: Substitute each such m_{12} in turn into (21), giving a set of four equations in three unknowns; solve (21) to find the least-squares solution for m_{14} , m_{24} , and m_{34} . Finally, accept the root of (22) that leads to the best least-squares solution. One could do this the other way round as well starting by considering the roots of (23) and accepting the best of the four solutions found. A different strategy is to choose m_{12} to be the number that is closest to being a root of each of (22) and (23). This is the algorithm that we have implemented, with good results so far.

To obtain the best results, however, it is probably necessary to take the conditions of Proposition 4 into account explicitly and compute an LP fundamental matrix satisfying these conditions using explicit assumptions about the source of error to formulate a cost function to be minimized. This has been shown to be the best approach for perspective cameras [21], [16].

The question of numerical stability is important in implementing algorithms using the linear pushbroom model. In particular, it is easy to encounter situations in which the determination of the linear pushbroom model parameters is very badly conditioned. In particular, if a set of ground-control points lie in a plane or are very close to being planar, then it is easily seen (just as with perspective cameras) that the determination of the model parameters is ambiguous. We have developed techniques (not described here) for handling some cases of instability, but care is still necessary. The algorithms described in this paper can not be used in cases where the object set lies in a plane.

6 SCENE RECONSTRUCTION

Once two camera matrices have been determined, the position of the points \mathbf{x}_i in space may be determined by solving (15). This will determine the position of the points in space up to an affine transformation of space.

In the case where both point matches between images and ground-control points are given, the scene may be reconstructed by using the matched points to determine the scene up to affine transformation, and then using the ground-control points to determine the absolute placement of the scene. If the ground control points are visible in both images, then it is easy to find the correct affine transformation. This is done by determining the position of the ground control points in the reconstructed image, and then determining the 3D affine transformation that will take these points on to the absolute ground-control locations.

If ground-control points are available that are visible in one image only, it is still possible to use them to determine the absolute location of the reconstructed point set. A method for doing this is given in [4] and will not be repeated here.

7 EXPERIMENTAL RESULTS

Two key assumptions are made in the derivation of the linear pushbroom model (see Section 2). In the context of remote sensing applications, the first assumption is that during the time of acquisition of one image the variations in velocity of the satellite in its orbit are negligible. In addition, the motion of the earth's surface can be included in the motion of the satellite, the composite motion being approximately rectilinear. The second assumption is that the rotation of the local orbital frame as well as the fluctuations of orientation with respect to this frame can be ignored. To what extent these assumptions are justified is explored in this section and several experiments that measure the accuracy of the linear pushbroom model are described.

In the first experiment, the accuracy of the linear pushbroom model was compared with a full model of SPOT's

HRV camera. This model, which is detailed in [22], takes into account the orbital dynamics, earth rotation, attitude drift as measured by on-board systems, ephemeris data, and several other phenomena to emulate the imaging process as accurately as possible. A different model is discussed in [23].

The linear pushbroom model was compared with the full model on a pair of real images with matched points computed using a stereo matching algorithm. A stereo pair of SPOT images of the Malibu region, centered approximately at 34 degrees 5 minutes north and 118 degrees 32 minutes west (images with (J, K) = (541, 281) and (541, 281) in SPOT's grid reference system [24]) were used. We estimated the camera models for these two images using a set of 25 ground control points, visible in both images, picked from USGS maps and several automatically generated image to image correspondences found using STEREOSYS [25].

Two performance metrics were computed. The accuracy with which the camera model maps the ground points to their corresponding image points is important. The RMS difference between the known image coordinates and the image coordinates computed using the derived camera models was measured. An application-specific metric, viz., the accuracy of the terrain elevation model generated from a stereo pair, was also measured.

Once again, the data was modeled using a perspective camera model, a linear pushbroom model and a full pushbroom model.

In order to make the results directly comparable, the same ground control points and image-to-image correspondences were used for camera model computations in all three experiments. (The number of points used for computation of the perspective camera is an exception where 511 image-to-image correspondences, instead of 100, were provided in an attempt to boost its accuracy.) In addition, the terrain model was also generated using the same set of matched points.

The results of these three experiments are tabulated in Table 1. The first and the second rows list the number of ground control points and the number of points used in the camera model computation. The third row gives the number of image-to-image matched points for which a point on the terrain was generated. The camera model accuracy, that is, accuracy with which a ground point $(x, y, z)^T$ is mapped into its corresponding image point, is listed in the fourth row. Finally, the RMS difference between the generated terrain and the ground truth (DMA DTED data) is given in the fifth row.

TABLE 1
A COMPARISON OF THE THREE CAMERA MODELS

	Pin-hole Model	Linear Pushbroom Model	Full SPOT Model
Num. gc pts	25	25	25
Num. match pts	511	100	100
Num. terrain points	68,131	68,131	68,131
RMS error	11.13 pixels	0.80 pixel	0.73 pixel
Terrain accuracy	380.79 m	35.67 m	11.10 m
Time	~5 sec.	~5 sec.	>20 min.

The attempt to model SPOT's HRV cameras by perspective cameras yielded camera models with a combined accuracy of about 11 pixels. This is a large error because for a high platform such as a satellite, even a single pixel error can translate into a discrepancy of tens of meter along the horizontal and vertical dimensions (the exact amount depends on the pixel resolution and the look angles). This is reflected in the accuracy of the generated terrain which is as much as 380 meters off, on the average. Thus, as expected, a perspective camera is a poor approximation for pushbroom camera. The linear pushbroom, on the other hand, is quite competitive with the detailed model, both in terms of camera model accuracy, as well as the accuracy of the generated terrain.

The last entry on the fifth row (the 11.10 m accuracy for the terrain generated by the complex model) is a little misleading since generated terrain is more accurate than the claimed accuracy of the ground-truth it is being compared with. This figure is a statement about the accuracy of the ground-truth, instead of the other way around.

Fig. 3 and Fig. 4 show the terrain generated by the perspective and the full SPOT models, respectively. Fig. 4 can be regarded as the ground truth. Since the area covered by the stereo pair is rather large (about 60 km \times 60 km), the terrain relief is shown only for a 1,024 \times 1,024 sub-image and has been considerably exaggerated compared to the horizontal dimensions. We have not included the terrain generated by the linear pushbroom model because it is visually indistinguishable from that generated by the full model (Fig. 4).

Fig. 3. Terrain reconstructed from perspective model.

Fig. 3 illustrates the distortion introduced when a partially perspective projection is modeled by a fully perspective camera. In order to understand this distortion better, the following experiment was conducted.

Using the full pushbroom model parametrized to an actual orbit and ephemeris data, and an artificial terrain model, a set of ground to image correspondences were computed, one such ground control point being computed

Fig. 5. Error profile for linear pushbroom model.

every 120 pixels. This gave a 51×51 grid of ground-control points covering approximately $6,000 \times 6,000$ pixels. Next, these ground control points were used to instantiate the linear pushbroom model using the algorithm of Section 3. In this experiment, the locations of ground points were fixed for both the full and linear pushbroom models. The difference was measured between the corresponding image points as computed by each of the models. The absolute value of error as it varies across the image is shown in Fig. 5. The maximum error was less than 0.4 pixel with an RMS error of 0.16 pixel. As can be seen, for a complete SPOT image, the error incurred by using the linear pushbroom model is less than half a pixel, and much less over most of the image.

To test whether a perspective camera model could do as well, the same set of ground control points were modeled using a perspective camera model. The result was an RMS error of 16.8 pixels with a maximum pixel error of over 45 pixels. Fig. 6 shows the error distribution across the image.

8 CONCLUSION

The Linear Pushbroom model gives a very good approximation to a full model of an orbiting pushbroom sensor, but is substantially less complex. The simplicity of Linear Pushbroom camera model allows many of the standard photogrammetric problems, such as camera calibration and pose detection, and relative orientation to be solved using simple noniterative algorithms. Apart from the application to orbiting satellite sensors, where the Linear Pushbroom model represents an approximation to the full orbiting model, the LP model has applications in industrial sensing. It has been used for the X-ray inspection of turbine blade parts. In this case, the Linear model is a very close approximation to the true geometry, and the sensor may be very accurately calibrated using the linear algorithms described in this paper.

Rajiv Gupta is currently pursuing his MD degree at Cornell University Medical College in New York City. He is also a computer scientist at the General Electric Corporate R&D Center, Schenectady, N.Y. Prior to his position at GE, he was a research assistant professor of electrical engineering (1988–1990) and postdoctoral research fellow (1987–1988) at the University of Southern California, Los Angeles. Dr. Gupta received a PhD degree in computer science from the State University of New York at Stony Brook.

He also holds a BE degree in electrical engineering and an MSc degree in physics, both from the Birla Institute of Technology and Science, Pilani, India. Dr. Gupta has more than 10 years' experience in computer vision, system integration, and VLSI. At the GE R&D Center, he has worked on design and implementation of diverse set systems, including systems for 3D reconstruction from stereo mammograms, 3D reconstruction of vasculature from digital subtraction angiograms, calibration of X-ray angiography gantries, and 2.5D X-ray metrology for nondestructive testing. While at USC, he designed the Cbase framework for integrating VLSI CAD tools. Dr. Gupta has published more than 50 research articles on medical imaging, photogrammetry, X-ray metrology, VLSI testing, and object orientation. He is a coeditor for *Object-Oriented Databases With Applications to CASE, Networks, and VLSI CAD* (Prentice Hall, Inc.). He is a member of IEEE and a recipient of the National Science Talent Search Scholarship awarded by the Government of India.

Richard I. Hartley received his BSc degree in mathematics from the Australian National University and MSc and PhD degrees also in mathematics from the University of Toronto. He also holds an MS degree in computer science from Stanford University. He has held various research positions in mathematics at the University of Frankfurt, Germany; Columbia University, New York; and Melbourne University, Australia—carrying out research in the area of 3D geometric and algebraic topology. Since 1985, he has been

employed at GE's Corporate Research and Development Center, where he has carried out research in the areas of VLSI CAD, rapid prototyping of electronic systems, DSP circuit design, and computer vision. His interests include automated techniques for DSP chip and multichip module design. He was the lead developer of the Parsifal silicon design system, which is used extensively within GE, and he has recently published a book on digital serial computation, describing that work. In recent years, Dr. Hartley has concentrated much of his research effort in the areas of computer vision and photogrammetry, particularly related to camera modeling and structure from motion from uncalibrated images, as well as industrial and medical applications of computer vision techniques. He is the author of more than 70 research papers on photogrammetry, geometric topology, geometric voting theory, computational geometry, and CAD and holds 30 U.S. patents in the areas of CAD, circuit design, DSP design, and industrial and medical imaging.
